Universal Specificity Investigation 7: Determining Which Frame is Universally Stationary

Daniel Harris
Northrop Grumman
Morrisville, USA
daniel.harris2@ngc.com

Prior investigations into the theory of universal specificity (or specificity for short) found a proper conception of time missed in common practice; which led to the realization that a universally stationary frame must exist; which led to the discovery that for any inertial reference frame the average effective speed of light, c_0, is less than or equal to c, and equal in all directions; which led to discovering the cause of kinetic time dilation; which led to revisiting the relativistic kinetic energy and total energy model; which finally allowed for the integration between potential and kinetic time dilation and an updated total energy model comprised of internal, kinetic and potential energy.

The most important takeaway from this investigation thus far is this: the difference in power between properly formed and ill-formed concepts is the difference between scientific progress and stagnation. Using what has been discovered, this investigation now turns to a means to objectively measure the universally stationary frame.

1. Universal Inertial Frame

A *universally stationary frame* (USF) is the only inertial reference frame that is still (no velocity) in the universe. There is such a frame for rotation, where it is easy to measure which frame has no angular velocity. A simple water in a buck experiment can tell you if the frame is rotating or not. If the bucket is rotating the surface of the water will create a bowl shape, and if it is not rotating, then the surface will be flat, as shown in Figure 1.

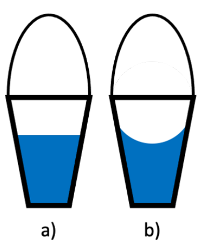

Figure 1. a) Non-rotating bucket of water. b) Rotating bucket of water.

A similar experiment cannot determine if a reference frame has velocity relative to the USF, as shown in Figure 2.

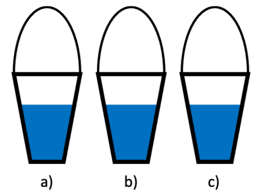

Figure 2. a) Universally stationary. b) Velocity is $0.5c$. c) Velocity is $0.\overline{9}c$.

Michelson and Morely tried (and failed) to determine the relative motion of earth with respect to the USF by measuring the difference in velocity of light from the same source at different points in earth's orbit, but instead demonstrated the interesting fact that the speed of light measured in any inertial frame is constant [1], or at least the average relative speed of light is constant [2] (also see investigation 2). Something is special about translational velocity, as compared to rotational velocity, where any inertial frame at any velocity appears to be stationary, while rotational velocity is imediately noticeable.

Several experiments have been devised that might measure motion relative to the USF, given the correctness of different theories [2]. Our aim in this investigation is, given the correctness of specificity, to devise another experiment that can objectively measure motion relative to the USF.

To begin, you might have noticed a peculiarity about kinetic time dilation, which is that despite the unit changes caused by work done, all pair-wise reference frames seem to agree on their respective relative velocity between each other. This is our first clue as to why all inertial frames seemed stationary up to this point, and doing a quick survey of the unit changes reveals why velocity is special.

2. A Survey of Unit Changes

We know that the units of measurement change for space and time when work is done, but why not velocity? Velocity, being a ratio of a change in distance to a change in time, means the change in units of velocity involves a change in units of the parts to this ratio, as shown in Equation (1).

$$v = \frac{dx}{dt} \tag{1a}$$

$$v' = \frac{dx'}{dt'} \tag{1b}$$

$$\frac{dx}{dx'} = \frac{dt}{dt'} = \sqrt{1 - \frac{\Delta e_K}{e_T}} \tag{1c}$$

$$\therefore v = \frac{dx'\sqrt{1-\frac{\Delta e_K}{e_T}}}{dt'\sqrt{1-\frac{\Delta e_K}{e_T}}} = \frac{dx'}{dt'} = v' \; \blacksquare \tag{1d}$$

This ratio of distance to velocity cancels the effect of change in units. This is what makes velocity special. All attempts to date to measure motion relative to a USF has relied on measuring velocity, which have thus far proved incapable of detecting the USF. It is not difficult to see why such attempts have failed to detect the USF, since the only effect of being in an inertial reference frame different from the USF is a change of units caused by work done, so of course we ought to expect a failed detection if we use a measurement where the effect is nullified.

What is required to objectively measure the USF is to use a measurement that does not nullify the effect of being in a reference frame different from the USF. What is required is a means for the unit change caused by work done to point us in the direction of a USF.

3. How to Objectively Measuring the Universal Inertial Frame

Experimenting with acceleration appears to be where we must first look to detect the USF, since acceleration involves a ratio that does not nullify the effect of a unit change. In fact, if one takes a closer look at the bucket experiment, one notices that this test must succeed for some other reason besides rotational velocity since rotational velocity must cancel unit changes too. The property of the bucket test that makes detecting the inertial rotation frame is, therefore, rotational acceleration. Rotational velocity only correlates to the test result, but it does not cause it—acceleration causes both.

We, therefore, need a similar test involving translational acceleration. Two forms of acceleration are known, kinetic acceleration and gravitational acceleration. Only gravitational acceleration ends up being useful.

A kinetic acceleration experiment might involve studying unit changes caused by accelerating a rocket to Alpha Centauri and back, like in the twins paradox setup. The problem with this experiment is that it would rely on remote measurements, which takes time and distance to make these kinds of measurements. The best form of remote measurement involves using photons, like LADAR, to make estimates of speed (via Doppler frequency shifts) and estimates of distance (via lap time of returns). Therefore, this experiment depends on the speed of light traveling for some time and distance, which nullifies the effects we are attempting to measure. This experiment, therefore, has to fail in detecting the USF.

A gravitational acceleration experiment might involve using six identical gravimeters, like the one derived in an earlier investigation, shown in Figure 3. If the test is set up appropriately, and given that the specificity is correct, then this next experiment will reveal where the USF is.

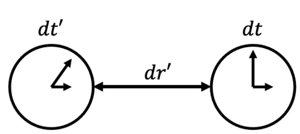

Figure 3. **Gravimeter.**

Recall from a prior investigation (see investigation 5) into specificity that the gravimeter is measuring two rates of change in time, dt and dt', via identical clocks some distance, dr', apart from each other. Additionally, dr' is normal to the time dilation gradient, and dt' is farther from the center of mass than dt. Lastly, these measurements translates to gravitational acceleration as shown in Equation (2).

$$\text{Let}: \ \nabla\tau^2 = \frac{\tau^2}{dr'} = \frac{\left(1 - \left(\frac{dt}{dt'}\right)^2\right)}{dr'} \tag{2a}$$

$$g(r') = \lim_{dr' \to 0} -e_T \nabla\tau^2 \tag{2b}$$

The gravimeter in this experiment would measure the gravitational acceleration of a massive object, but in three orthogonal dimensions (two gravimeters per dimension). The speed of each gravimeter would be equivalent, measured in the massed object's reference frame (MOF), and directed towards its center of mass. two of three dimensions are shown in Figure 4. (Note: in and out of paper dimension is not shown).

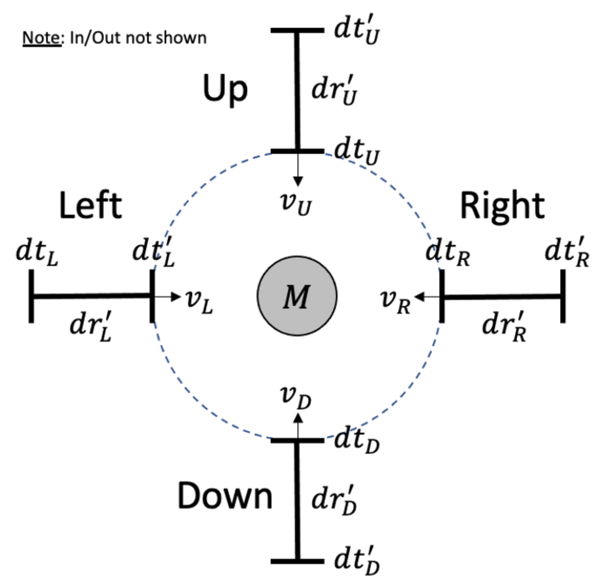

Figure 4. **USF detection experiment.**

How this experiment works is that the gravimeter's clocks take a measure of dt and dt' once the forward clock reaches some marked threshold some radius from the center of mass, as measured from the center of mass' inertial reference frame. Each gravimeter, being identical and calibrated to the same initial inertial reference frame, assumes dr' is the same under any condition; however, the radial location where dt' is measured changes since the units subsumed under dr' physically changes in different frames due to length contraction. Any changes to the ratio $\frac{dt}{dt'}$ in Equation (2) due to kinematic time dilation is nullified, in the same way it is nullified for velocity; therefore, the only change in the ratio $\frac{dt}{dt'}$ will be due to changes in the location where dt' is measured.

Once gravitational acceleration is measured, a direct solution backing for the velocity of the massed object relative to the USF might not be possible because of the set of non-linear equations.

However, a simulation can run the set of possible velocities relative to the USF and experimental results can be compared to simulated results. That way the simulated results that line up with experimental results will indicate the estimated velocity we seek. Subtracting that velocity from the MOF tells us where the USF is.

Even though we lack experimental results, a simulation was ran of a notional case to demonstrate how this simulated numerical solution would appear. In order to gain the necessary precision, the gravitational acceleration in orbit measured in the MOF, and the speed of all the probes in the MOF, had to be quite large. A simulation for a single dimension was ran (see code in Appendix), and the parameters for the executed simulation were:

- Mass of object: $1000\ [Solar\ Masses]$
- Original distance, dr', clocks were apart in MOF: $1\ [km]$
- Measurement distance from center of mass: $0.5\ [AU]$
- Speed of gravimeters in the MOF: $0.1\ [fraction\ of\ c]$

The results of this simulation can be seen in Figure 5. From the results we can see how the massed object's velocity in the USF (x-axis) affects the gravimeter readings (y-axis). Three gravimeters were simulated: an orbital gravimeter, a gravimeter traveling faster than the massed object in the USF (gravimeter1), and a gravimeter traveling slower (gravimeter2).

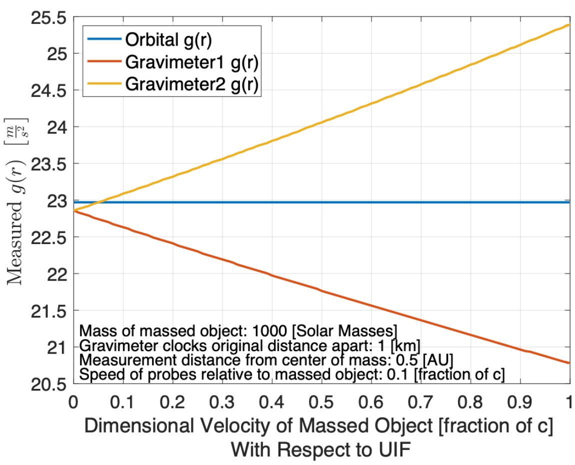

Figure 5. Simulated Results.

4. Conclusion

In conclusion, it was shown that it is possible to detect the USF if measurements are taken that do not nullify the effects of changes of units caused by work done. The designed experiment involving sending gravimeters hurtling towards the center of mass of a massive object is capable of such a detection, if the specificity and length length contraction is correct.

The last question to be investigated by this specificity series is: if spacetime is not a real thing, and therefore, cannot be responsible for any time dilation, as an environmental affect on objects, then what causes everything in the same reference frame to be effected by time dilation in the same way? Addressing that question is the focus of the next (and last) investigation.
